(57) **ABSTRACT**

A method and system for producing tomosynthetic images of a patient's breast. An x-ray source that delivers x-rays through a breast immobilized and compressed between a compression paddle and a breast platform and form an image at a digital x-ray receptor panel. Multiple x-ray images are taken as the x-ray source and the receptor move relative to the immobilized breast. In one preferred embodiment, the x-ray source travels from -15° to +15°. The source can travel in an arc around the breast while the receptor travels linearly while remaining parallel and at the same distance from the breast platform. The sets of x-ray image data taken at different angles are combined to form tomosynthetic images that can be viewed in different formats, alone or as an adjunct to conventional mammograms.

**X-RAY MAMMOGRAPHY WITH
TOMOSYNTHESIS****CROSS REFERENCE TO RELATED
APPLICATION**

This application is a continuation-in-part of patent application Ser. No. 10/305,480 filed Nov. 27, 2002, now U.S. Pat. No. 7,123,684 granted Oct. 17, 2006, and claims the benefit of the filing date thereof.

FIELD

This patent specification is in the field of x-ray imaging of the breast and, more specifically, obtaining and processing x-ray data for tomosynthesis.

BACKGROUND

Breast cancer remains an important threat to women's health. X-ray mammography currently is the most widely used breast imaging tool for early detection, and is the modality approved by the Food and Drug Administration to screen for breast cancer in women who do not show symptoms of breast disease. A typical mammography system takes a projection image of the compressed breast, using a collimated x-ray source at one side and a film/screen unit at the other side of the breast. In the United States, typically two views are taken of each breast, one from above (cranial-caudal, or CC) and one from the side (mediolateral-oblique, or MLO). The x-ray source is an x-ray tube typically operating at 25-40 kVp, using a molybdenum or rhodium rotating anode with a focal spot of about 0.3-0.4 mm and, in some cases, 0.1 mm or less. An anti-scatter grid between the breast and the film/screen unit reduces the effects of x-ray scatter. The screen converts x-ray energy to visible light to which the film is exposed to record the image. In each view, the breast is compressed to reduce patient motion and also for reasons such as reducing scatter, separating overlapping structures in the breast, making the thickness of the imaged breast more uniform, and providing more uniform x-ray exposure. Currently, flat panel array receptors are replacing the film/screen units in mammography systems. The Selenia™ digital mammography system with such a flat panel x-ray receptor is offered by Lorad, a subsidiary of the assignee Hologic, Inc. of Bedford, Mass. Digital mammography has significant advantages and in time may fully supplant film/screen systems. Additional information regarding digital mammography systems and processes offered by the common assignee can be found at <www.hologic.com>.

Mammograms, whether from film/screen units or from digital systems, are particularly difficult to read, and the rate of false negatives and false positives is significant. Many advances have been made in recent years in image acquisition and in image processing, but a need still remains to reduce the rates of false negatives and positives, at least in screening mammography. Additional information can be gained through modalities such as CT and MRI, but examination and interpretation time and cost and other factors have limited their use in screening for breast cancer. Ultrasound breast examination has been proposed as an adjunct to x-ray examination, with synthesized ultrasound images of thick slices of the breast as they would appear in the same projection view as an x-ray view displayed together with the x-ray view, and a unit taking both x-ray and ultrasound images has been proposed. See, e.g., Patent Application Publication No. U.S. 2003/0007598 A1 and U.S. Pat. No. 5,983,123. Digital tomosynthesis has been proposed for x-ray breast imaging, and a laboratory unit is believed to have been installed at the Massachusetts General Hospital (more than a year before the

2

filing date hereof), as reported in Wu, Tao, 2002, *Three-Dimensional Mammography Reconstruction Using Low Dose Projection Images*, PhD thesis, Brandeis University, incorporated here by reference. See, also, Patent Application Publication No. 2001/0038681 A1 and PCT application International Publication No. WO 03/020114 A2 published Mar. 13, 2003, both incorporated herein by reference. Digital tomosynthesis in more general contexts also has been proposed. See, e.g., U.S. Pat. Nos. 6,289,235 and 5,051,904, commonly assigned U.S. Pat. No. 4,496,557, and Digital Clinical Reports, Tomosynthesis. GE Brochure 98-5493, November 1998, all incorporated herein by reference. Reference markers can be used in x-ray imaging for purposes such as checking the rotation angle and unwanted shift of center of rotation of an x-ray source and receptor, and fiducial phantoms can be used in 3D angiography to calibrate for irregular scan geometries. See, e.g., U.S. Pat. Nos. 5,051,904, 5,359,637, and 6,289,235, N. Navab, et al., *Dynamic geometrical calibration for 3D cerebral angiography*, SPIE Vol. 2708, pp. 361-370, and said PCT published application WO 03/020114 A2, all incorporated by reference here.

It is believed that no breast tomosynthesis systems are commercially available currently for clinical use in breast imaging, and that improvements in x-ray imaging and tomosynthesis are a desired goal. Accordingly, it is believed that a need remains for improved and practical tomosynthesis mammography.

SUMMARY

In a typical x-ray imaging according to preferred embodiments disclosed in this patent specification, a patient's breast is immobilized, at the same or lower compression than in conventional mammography, between a breast platform and a compression paddle. The platform and paddle, and the breast between them, in turn are between an x-ray source and a digital imaging receptor. Unlike conventional x-ray mammography, in which typically a breast is imaged from only one angle at a given compression, here the immobilized breast is imaged with x-rays from the source that pass through the breast and impinge on the receptor, from a greater number of different positions of the source and receptor relative to the breast while maintaining the breast immobilized, to derive image data for the respective positions. To do this, the x-ray source moves around the immobilized breast, typically but not necessarily in an arc, and the receptor also moves relative to the breast, but in a motion that allows it to remain substantially parallel to the same plane. The x-ray data taken at each of a number of positions of the receptor relative to the breast is processed to form images where each of a number of the images is formed from image data acquired from two or more of the different positions, e.g., to form tomosynthetic images. The x-ray dose to the breast can be different for the different imaging positions. One or more of the imaging positions can use an x-ray dose comparable to that used for conventional mammography. These positions may be the same or similar to the source/receptor positions for the typical views used in conventional mammography, e.g., the CC view and the MLO view. Fiducial markers can be used to help assess the positions of the x-ray source and x-ray receptor relative to each other and/or the breast being imaged, and for other calibration purposes. The fiducial markers can be integrated with the compression paddle and/or the breast platform, or can be positioned otherwise to serve the intended purpose. The immobilized breast can be imaged at angular positions extending over a selected range around the immobilized breast, for example $\pm 15^\circ$, although other ranges can be used in other examples. The motion can be continuous over some or all of the imaging positions, or can be intermittent such that

the x-ray source and/or the x-ray receptor stop for taking and image and then move to the next position for the next image.

An antiscatter grid can be used, positioned between the breast platform and the x-ray receptor while x-ray image data are taken. One example is the grid available from Lorad under the tradename HTC® grid. Alternatively, the image data at some or all of the imaging positions can be taken without an antiscatter grid that is external to the x-ray receptor. Rather than using the currently conventional materials for the x-ray emitting target in an x-ray tube serving as the x-ray source, in one of the preferred embodiments the target is made essentially of Tungsten, to provide x-rays at energies that are believed more suitable for breast x-ray tomosynthesis. Geometries other than an x-ray source that rotates around the immobilized breast and an x-ray receptor that moves relative to the breast and the source but remains in substantially parallel to the same plane, can be used.

Image data taken at the different imaging positions can be processed to generate tomosynthetic images of selected slices of the breast. The images can be of thin slices, essentially planar sections through the breast, as in CT slices. Alternatively, they can be of thick slices of the breast, e.g., slices that are about 0.5 cm to about 1.0 cm thick, and simulate projection images of slices of that thickness, projected on one or more selected image planes. In one example, the image plane or planes of the thick slice images are the same as those of the typical conventional mammograms, and can be displayed for viewing in appropriate groupings. For example, projection-like tomosynthetic images of thick slices on a plane parallel to that of a conventional CC image can be displayed together with a conventional CC image of a breast, on the same screen or adjacent screens or other displays. Similarly, projection-like tomosynthetic images of thick slices on plane parallel to that of an MLO image can be displayed on the same display or on adjacent displays with a conventional MLO mammogram of the same breast. In the alternative, the image planes of the tomosynthetic images can be at one or more selected angles to the image planes of the typical images used in screening x-ray mammography.

Tomosynthetic images can be formed using a form of filtered backprojection modified by using a filter function that is significantly different from a conventional ramp filter used in CT technology backprojection. The novel filter function is believed to be uniquely suited to breast tomosynthesis. In particular, in the frequency domain the novel filter function at low spatial frequencies is much steeper than a CT technology ramp function, it is close to an all-pass filter at intermediate frequencies, and at higher frequencies it falls off to suppress fine detail noise.

BRIEF DESCRIPTION OF THE DRAWING

FIG. 1 illustrates schematically a front view of an x-ray source, a breast immobilized between a compression paddle and a breast platform an antiscatter grid and an image receptor, where the x-ray source and the x-ray receptor move relative to the breast for imaging the breast at different angles according to a preferred embodiment.

FIG. 2 illustrates a side view of the system illustrated in FIG. 1 and additional components of a system according to a preferred embodiment.

FIG. 3 illustrates a display arrangement showing both images that are the same or similar to conventional mammograms and tomosynthetic images according to a preferred embodiment.

FIG. 4 illustrates in graph form a backprojection filter in the frequency domain used in a preferred embodiment, compared with a conventional ramp filter used in CT technology and an all-pass filter.

FIG. 5 illustrates coordinate values of a backprojection filter according to a preferred embodiment as control point values in the frequency domain in log scale.

FIG. 6 illustrates the use of fiducial markers.

FIGS. 7 and 8 are similar to FIGS. 1 and 2, respectively, but illustrate another preferred embodiment.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

FIG. 1 schematically illustrates in front view an x-ray source **100** in three different positions **100a**, **100b** and **100c**, between which source **100** moves in an arc centered at the top center of a patient's breast **102** immobilized between a compression paddle **104** and a breast platform **106**. An antiscatter grid **108** is immediately below breast platform **106**, and an x-ray receptor **110** is below grid **108**, and is shown in three different positions, **110a**, **110b**, and **110c**, corresponding to the illustrated positions of source **100**. Receptor **110** moves relative to immobilized breast **102** along a path substantially parallel to breast platform **106** and maintains substantially the same distance from platform **106**, as indicated by the arrows in FIG. 1. In operation, source **100** moves from one of its illustrated position to another, and so does receptor **110**. At each position of source **100** and receptor **110**, source **100** is energized to emit a collimated x-ray beam, of which only the center ray is illustrated. The beam irradiates breast **102** and some of the radiation that has passed through the breast also passes through grid **108** and is received by receptor **110**. As in known in the art, receptor **110** and associated electronics generate image data in digital form for each pixel of a rectangular grid of pixels at each of the illustrated angular position of source **100** and translation positions of receptor **110** relative to immobilized breast **102**. While only three positions are illustrated in FIG. 1, in practice image data is taken at each of a much greater number of positions, for example, at every 1° of an arc of ±15° of source **100** around immobilized breast **102**. The taking of image data can be while source **100** and receptor **110** are stopped at their respective positions, after moving from one position to the next. In a different preferred embodiment, the motion of one or both of source **100** and receptor **110** can be continuous, with a respective set of image data being accumulated over a small increment of continuous motion, say a 0.1° to 0.5° arc of motion of source **100**. These parameters are only an example. Different preferred embodiments can use different ranges of motion of source **100** and receptor **110**, and can use a motion of source **100** that is arcuate and centered at a different point, such as in immobilized breast **102** or at breast platform **106** or at grid **108** or at receptor **110**, or a motion that is not arcuate but is translational or is a combination of different types of motions, such as partly translational and partly rotational. In the most preferred embodiment, the source **100** motion is arcuate and the receptor **110** motion is translational. As described further below, in practice source **100** can be integrated in a C-arm that is the same or similar to the C-arm used in the commercially available Selenia® or MIV mammography systems available from Lorad, and receptor **10** can be the same receptor as used in such commercially available systems but mounted differently so that it translates in a plane substantially parallel to breast platform **106** while maintaining a substantially constant distance from platform **106** rather than rotating as a unit with source **100**, as in Lorad commercially available systems.

FIG. 2 schematically illustrates a side view of a mammography system using the arrangement of FIG. 1. In FIG. 2, x-ray source **100** is at one end **200a** of a C-arm **200** that is supported for selective rotation about an axis **202**, independently of a support **204** for compression paddle **104** and breast platform **106**. Support **204** also selectively rotates about the same axis **202**. The other end **200b** of C-arm **200** interacts

with x-ray receptor **110** through a motion translator schematically illustrated at **206** that translates the rotational motion of the end **200b** about axis **202** to a substantially translational motion of receptor **110** that substantially maintains the distance of receptor **110** from breast platform **106** while x-ray data is being taken. FIG. 2 is not to scale, and receptor **110** can be spaced further from member **200b** than illustrated, to allow more space for motion translator **206**, and also to allow for receptor **110** to be moved selectively further from or closer to breast platform **104** and thus allow for x-ray image magnification. In operation, C-arm **200** and support **204** are rotated to desired angular positions, either manually or by motor drives, patient breast **102** is positioned on platform **106** and is immobilized by bringing paddle **104** toward platform **106** and compressing breast **102**, with typically the same or less force than for a typical conventional mammogram, such as between one to one-third the conventional force. With breast **102** immobilized, and with C-arm at a selected angle relative to a normal to platform **106** and receptor **110**, such as $+15^\circ$, imaging starts, and a projection image is taken for each of a number of selected angular positions of source **100** while C-arm **200** rotates, continuously or intermittently, through a selected angle, such as an angle of 30° , is from $+15^\circ$ to -15° . Of course, the motion can be in the opposite direction, from -15° to $+15^\circ$, or can be over a different angular interval, such as over less than a total of 30° , e.g. 25° , 20° , etc., or more than 30° , such as 35° , 40° , etc. Currently, the preferred range is $\pm 15^\circ$. A set of image data can be taken at selected angular positions, such as every degree, or every fraction of a degree, or every several degrees of angle. The angular increments between the different positions for sets of image data need not be the same. For example, the increments around 0° can be less than those at the extremes of the angular positions, or vice versa. Currently, the preferred angular increment is 3° . The sets of image data can be taken after an incremental motion from one angular position of source **100** to another, and from one translational position of receptor **110** to another, such that source **100** and receptor **110** are stationary while a set of image data is being taken. Alternatively, one or both of source **100** and receptor **110** can move continuously while sets of image data are being taken, one set for each increment of continuous motion. In the currently preferred embodiment, in the example of continuous motion while taking image data both source **100** and receptor **110** move while image data are being taken.

FIG. 2 also illustrates schematically an electrical/electronic system **208** that interacts with the components discussed above. System **208** includes a control **210** for selectively energizing and otherwise controlling x-ray source **100**, an arm rotation control **212** for selectively rotating C-arm **200** and support **204**, a breast compression control **214** for selectively moving compression paddle **104** toward and away from breast platform **106**, data readout electronics **216** coupled with x-ray receptor **110** to read out the sets of image data at the respective positions of source **100** and receptor **110** relative to immobilized breast **102**, and an image reconstruction and display unit **218** coupled with data readout electronics **216** to receive the sets of image data from electronics **216** and to process the image data for reconstruction and other purposes and display images.

For a given position of breast **102**, such as a position that is the same or similar to the CC position for a conventional mammogram, source **100** and receptor **110** can be positioned relative to immobilized breast **102** such that at the 0° position a center ray of the x-ray beam from source **100** would be substantially normal to receptor breast platform **106** and receptor **110**. For a first set of image data, source **100** is at $+$ (or $-$) 15° in a preferred example, and is gradually moved, continuously or intermittently to $-$ (or $+$) 15° , with a set of image data taken every 3° . The angular range and the incre-

ment over which data sets are taken can each be selectively set by the operator, depending of characteristics of the breast being imaged and the screening and diagnostic needs, and can be different for different patients or from one to the other breast of the same patient. For example the source can move through angles that range from a fraction to a degree to several degrees from one imaging position to the next. Each set of image data is supplied by image readout **216** for processing at image reconstruction and display unit **218**. Each set of image data can be taken at the same x-ray dose to the breast, and the dose at any one of the different imaging positions can be substantially less than that for a conventional mammogram. The x-ray dose can be substantially the same for each imaging position, but preferably the dose at one of the position, e.g., at or close to the 0° position, is the same or similar to dose for a conventional mammogram while the dose at the each of the other positions is less, preferably much less. Alternatively, the scan can begin with or end with an exposure close to the 0° position at a dose similar to a conventional mammogram, and the rest of the set of image data can be over the angular range with each exposure at an x-ray dose that is substantially less than that for a conventional mammogram. Thus, two types of images can be produced in accordance with the currently preferred embodiment while breast **102** is immobilized in the same position. One type is the same or is at least similar to a conventional mammogram, which can be read and interpreted in the manner familiar to health professionals. The other type is tomosynthetic images reconstructed from the image data and displayed either separately or as an adjunct to the display of the image that is the same or similar to a conventional mammogram. The process described above for one position of breast **102** can be repeated for another position. For example one process can be for a breast position in a manner that is the same or similar to positioning the breast for a conventional CC view, the breast can then be released, the support **204** and C-arm **200** rotated to other angular positions and the breast repositioned in a manner that is the same and similar to the position for an MLO view, and the procedure repeated.

FIG. 3 illustrates schematically a display according to a preferred embodiment, where **300** is a display that is the same or similar to a display for a conventional CC mammogram of two breasts and **302** is a similar display for a conventional MLO view. Another display **304** is close to display **300** and can display any one or more of several types of tomosynthetic images reconstructed from the image data taken at the different imaging positions. For example, if display **300** shows views of a right breast taken at or close to the 0° position in one imaging sequence of a total rotation of source **100** over the $\pm 15^\circ$ range, display **304** can show, at the option of the user, any one or more of the following views of the right breast: (1) one or more of the projection views taken at the different imaging positions; (2) one or more of several tomosynthetic views of thick slices of the right breast simulating projection views of the right breast taken at the same or similar angle as the view at display **300**, with the slices having effective thicknesses selected by the user, such as from several mm to something less than the thickness of the immobilized breast, typically from several mm to about 1 cm; (3) one or more tomosynthetic views of thin slices of the right breast, each simulating a slice through the breast in a respective plane parallel to that of the view at display **300**, where each thin slice has an effective thickness of about a mm or less; (4) thin and/or thick slices corresponding to planes that are not parallel to that of the view at display **300**; (5) a scrolling image through any of the slices discussed above; and (6) a selected combination of the above displays. A similar display **306** can be associated with display **302**, and show a similar selected views related to the images at display **302**. FIG. 3 illustrates only one example according to preferred embodiments. Other

arrangements also are contemplated, such as different windows on the same display for the different images, differently positioned displays, etc. The user can select the type of images for display, the thickness of a thick slice or a thin slice, the orientation of the slices for display, which slices to display where and in what order, whether to display thick or thin slices as static slides or to scroll through slice images as in movie, etc. Controls 306 can be coupled to each of the displays, and can include manual inputs such as a joystick and/or other known interface devices and a suitably programmed computer to allow a user to control the images that are displayed. For example, the controls can include: (1) selecting one or more areas or volumes of interest at one or more of the displayed images and further processing the image data to form and display additional images of the area or volume of interest (for example, if a lesion is identified that is between tomosynthetic thin slices 32 and 37, the user can manually designate the corresponding area or volume and command the display of the thin slices in that area or volume, and other parameters such as the orientation of the thin slices); (2) identifying the position of an area or region of interest for use in additional procedures such as needle biopsy (for example, the user can designate with a cursor or in some other way a point in or an outline of a suspected lesion in the breast, and the xyz coordinates of the designated point, area, or volume); (3) the user can manually designate the desired thickness, arrangement, and other parameters of slices whose images are to be displayed, to thereby display images of slices that have user-selected thicknesses and other parameters, such as orientation, so that images of slices of different thicknesses and/or orientations can be displayed concurrently; and (4) the user can point to an area of interest in one of the displayed images and the system can automatically display one or more markers at corresponding or at least related locations in one or more of the other images that are being concurrently displayed.

At each imaging position, receptor 100 generates respective digital values for the pixels in a two-dimensional array. In one example, receptor 110 has a rectangular array of approximately 4096 by 3328 pixels, with a pixel size of approximately 70 micrometers in each of the column and row directions. The image data of a set (for a respective imaging position) can be processed either at the full spatial resolution of receptor 110, or at a lower effective spatial resolution, e.g., by binning several original pixel values into a single, combined pixel value. For example, each set of 2x2 adjacent pixels can be combined into a single respective pixel value, thus achieving an effective spatial resolution of 140 micrometers in each direction. The binning can be in some other combination of original pixels, such as 2x3, and can be done by data readout electronics 216 or image reconstruction and display unit 218 (FIG. 2).

Image reconstruction is done using backprojection in the spatial domain or in the frequency domain as in CT technology but with a novel filter that differs from the ramp filter (in the frequency domain) used in CT reconstruction. See, e.g., G. Lauritsch, et al., *A theoretical framework for filtered back-projection in tomosynthesis*, SPIE Medical Imaging Conference, Vol. 3338, 1998, and U.S. Pat. No. 6,442,288, both incorporated here by reference. Referring to FIG. 4, the novel filter is represented by graph 400, while a graph 402 represents a conventional CT ramp filter, and a graph 404 represents an all-pass filter. As seen in FIG. 4, the novel filter according to a preferred embodiment rises sharply in amplitude at lower frequencies, between points a and c (in the range indicated at b), as compared with the conventional ramp filter, then levels off at intermediate frequencies to become the same as or close to an all-pass filter between points c and d, and then gradually drops off at higher frequencies. Using the novel

filter produces significantly better breast images compared to using a conventional CT technology ramp filter.

FIG. 5 gives a sense of the values of the low, intermediate and high frequencies discussed in connection with FIG. 5. In FIG. 5, the frequency axis is plotted on log scale, and typically is related to spatial resolution of a few mm or more, i.e., it affects mainly to overall impression and flatness of the reconstructed image. With suitable suppression of low frequency content through frequency dependent weights defined by the shape of the novel filter, and gradual suppression of high frequency noise, a tomographic image with good image contrast at all frequency scales can be reconstructed and presented in accordance with a preferred embodiment. Preferably, the filtered backprojection reconstruction of tomographic images is carried out in the frequency domain, using well known processes with the novel filter. However, comparable filtered backprojection can be carried out in the spatial domain, as in known in CT technology, using direct convolution of image data with the spatial domain representation of the filter represented in the frequency domain in FIGS. 4 and 5. In either the frequency domain or in the spatial domain the novel filter can be applied to the image data to generate filtered data for backprojection, or backprojection can be carried out first, followed by a filtering operation. The reconstruction process preferably uses the direct fan-beam backprojection method known in CT technology, but with the novel filter, although it may be possible to use the image data to simulate sets of parallel beam paths for backprojection. The reconstructed thin slice images form a three-dimensional image of the breast, comprising voxel values for respective incremental volumes. These voxel values can then be combined as known in CT technology to synthesize any selected thin slice or thick slice in any selected orientation, and in any selected projection plane.

In a preferred embodiment, while each of all or most of the imaging positions uses lower x-ray dose than that of a conventional mammogram, higher KV can be used as compared with a conventional mammogram in order to boost signal levels from receptor 110 and improve signal-to-noise (SNR) ratios. In addition, preferable an x-ray tube with a Tungsten target is used to further exploit the advantage of higher kVp imaging of the breast, such as between 25 and 50 kVp with different x-ray beam filtration. A small focal spot, of the order of 1 mm or less, is preferred, although a larger focal spot of several mm can be used.

In other preferred embodiments, contrast enhanced breast tomosynthesis can be carried out, by obtaining tomosynthetic images as described above before injecting a contrast agent such as Iodine into the patient, then repeating the process after injection, and subtracting images of the pre-injection and post-injection sets. Another preferred embodiment involves time subtraction tomosynthesis, related to subtracting comparable images obtained at different times. Yet another is dual-energy breast tomosynthesis, whereby two tomosynthetic images at low and high energies are acquired and then subtracted, the two images being acquired through a process such as using successive scans at two different x-ray energy ranges or by alternating x-ray pulses of low and high energy to create the two images. Another other preferred embodiment involves obtaining and displaying both x-ray tomosynthetic images of a breast and ultrasound images of the same breast. Computer aided diagnosis, as known to those skilled in the art and as commercially used currently in the United States, can be applied to selected tomosynthetic images generated as described above.

Fiducial markers are used in preferred embodiments for off-line (without a breast) mechanical positioning and calibration and/or on-line (while imaging a breast with x-rays) image based positioning encoding of moving components.

The fiducial markers can be made of a material such as lead or another metal, and can be in the form of points or lines or arrows or crosses, at locations that would be imaged by the x-ray beam at receptor 110 simultaneously with the imaging of a breast 102 but outside the area of the breast image. The fiducial markers are integrated with compression paddle 104, or they can be at or near breast platform 106, or they can be supported separately from paddle 104, for example on a separate member that can be selectively brought into the path of the imaging x-ray beam or taken out of that path, e.g., to take an image that is the same or similar to a conventional mammogram. Different patterns or types of fiducial markers can be provided, for selection by the user. FIG. 6 illustrates an example of arranging fiducial markers 601, 602, 603 and 604 relative to an image of breast 102a on receptor 110, as seen in a top plan view when receptor 110 is horizontal and the fiducial markers are integrated in compression paddle 104.

An alternative embodiment, illustrated schematically in a front view in FIG. 7 and in side view in FIG. 8, is similar to the embodiment illustrated in FIGS. 1 and 2 except that receptor 110 is affixed to the end 200b of C-arm 200 that is opposite x-ray source 100. In this embodiment, receptor 110 moves relative to immobilized breast 102 along an arcuate path from one imaging position to another. Because the change in angle between receptor 110 and breast platform is small, it can be disregarded in processing the sets of x-ray image data. Alternatively, a geometric correction known to those skilled in the art can be applied to each set of image data to convert it to interpolated pixel values that would correspond to those that would have been obtained if receptor 110 had been parallel to and at the same distance from platform 106 at all imaging positions. The so corrected sets of image data can then be used in filtered back projections as described above.

In each of the embodiments of FIGS. 1-2 and FIGS. 7-8, antiscatter grid 108 may be selectively retractable, so that the user may take any selected set of x-ray image data with or without using grid 108. As is known in the art, grid 108 can be made to move relative to the x-ray beam during the taking of a set of image data. Similarly, the distance between breast platform 106 and receptor 110 can be selectively changed to effect magnification of the breast image recorded at receptor 110.

The invention claimed is:

1. A method of imaging a patient's breast with x-rays using a flat panel digital x-ray imager to obtain both two dimensional (2D) image data for a conventional mammogram data and three-dimensional (3D) image data for tomosynthesis images in a single breast compression, using an anti-scatter grid in obtaining some but not all the image data, comprising:

immobilizing a patient's breast between an x-ray source and a flat panel digital x-ray imager;

energizing the x-ray source to emit x-rays at each of a plurality of different angular positions of the source relative to the breast while the breast remains immobilized, and concurrently using the imager to derive x-ray projection image data for the respective positions;

wherein the image data for at least one of said positions, called hereafter a mammogram position, are taken at a view matching that of a conventional CC and/or MLO view used in conventional mammography, and the image data for a plurality of other positions, called hereafter tomosynthesis positions, are taken at other relative angles of the source and breast;

wherein the x-ray dose to the patient's breast when taking said image data for each of said tomosynthesis positions is less than the x-ray dose when taking said image data for said mammogram position, and the x-ray dose for said mammogram position is similar to a dose used for a conventional mammogram;

using an anti-scatter grid between the patient's breast and the imager for at least the mammogram position but not for at least some of the tomosynthesis positions; and processing the image data taken for the mammogram position to form and display a mammogram and using the image data taken for said tomosynthesis positions to form and display tomosynthesis images of the breast.

2. The method of claim 1, wherein the image data for each of said tomosynthesis positions are taken at a patient x-ray dose that is much less than for the image data for mammogram position.

3. The method of claim 1, wherein the step of energizing the x-ray source at different angular positions comprises energizing the source intermittently during a continuous movement thereof relative to the breast covering at least some said positions.

4. The method of claim 3, wherein the energizing step further includes energizing the source while stationary relative to the breast for at least one of said positions.

5. The method of claim 1, wherein the image data for the mammogram position are acquired when the source is stationary relative to the breast.

6. The method of claim 1, wherein the step of energizing the x-ray source at different angular positions comprises keeping the source stationary relative to the breast at a number of said positions.

7. The method of claim 1, wherein at least some of the tomosynthesis images conform to image planes that are generally parallel to that of the mammogram.

8. The method of claim 1, wherein at least some of the tomosynthesis images conform to image plane that are non-parallel to that of the mammogram.

9. The method of claim 1, wherein the source at said mammogram position is at an angle of substantially 0° at which a center ray of the x-rays is substantially normal to the x-ray imager.

10. The method of claim 1, wherein the image data for said mammogram position are taken before the image data for the tomosynthesis positions.

11. The method of claim 1, wherein the image data for the mammogram position is taken after the image data for the tomosynthesis positions.

12. The method of claim 1, wherein the image data for the mammogram position are taken after the image data for some of the tomosynthesis positions but before the image data for other tomosynthesis positions.

13. The method of claim 1, wherein the image data for each of the tomosynthesis positions are acquired with the use of substantially higher x-ray source kV compared with the kV used for the image data acquired at the mammogram position.

14. The method of claim 1, wherein the image data are acquired with x-rays emitted from a Tungsten x-ray target.

15. The method of claim 1, wherein at least some of the image data are acquired with x-rays at a kVp range substantially higher than 25 kVp but no more than 50 kVp.

16. The method of claim 1, wherein at least some of the image data are acquired with x-ray in a range from 25 kVp up to 50 kVp.

17. The method of claim 1, wherein said angular positions extend over a range of no more than 60°.

18. The method of claim 1 including displaying the mammogram and tomosynthesis images for concurrent viewing.

19. The method of claim 1 including displaying the mammogram and tomosynthesis images on the same screen.

20. The method of claim 1 including displaying the mammogram and tomosynthesis images on adjacent screens.

21. The method of claim 1, wherein the tomosynthesis images represent thin slices of the breast that are essentially planar sections through the breast.

22. The method of claim 1, wherein the tomosynthesis images represent thick slices of the breast, about 5 to about 10 mm thick.

23. A combination mammogram/tomosynthesis system comprising:

an x-ray source, a flat panel digital x-ray imager, and a breast support configured to immobilize a patient's breast between the source and the imager;

a source support configured to selectively move the source relative to the breast support between different angular positions of the source relative to the breast support;

a control configured to selectively energize the source to emit x-rays through the breast support to the imager, while a patient's breast remains immobilized in the breast support at each of said different angular positions; wherein at least one of said angular positions is a mammogram position that is the same or similar to a position for a conventional mammogram but others of said positions are tomosynthesis positions that are different from conventional mammogram positions;

wherein said x-ray source is configured to apply an x-ray dose to the patient's breast in each of said tomosynthesis positions that is less than the x-ray dose applied to the breast in said mammogram position, and the x-ray dose for said mammogram position is similar to a dose used for a conventional mammogram;

an anti-scatter grid configured to be selectively movable in the path of said x-rays from the breast to the imager, said grid being in said path for the mammogram position but being out of said path for at least some of the tomosynthesis positions; and

a processor configured to use an output of said imager for said mammogram and tomosynthesis positions of the source relative to the immobilized breast to form at least one mammogram image for display and tomosynthesis images of the breast for display.

24. The system of claim 23, wherein the control is configured to energize the source to emit a patient x-ray dose for each of the tomosynthesis positions that is much less than the patient x-ray dose for the mammogram position.

25. The system of claim 23, wherein the control is configured to energize the x-ray source at different angular positions intermittently during a continuous movement of the source relative to the breast covering at least some said positions.

26. The system of claim 23, wherein the control is configured to energize the source while the source is stationary relative to the breast for at least one of said positions.

27. The system of claim 23, wherein the control is configured to energize the source for the mammogram position when the source is stationary relative to the breast.

28. The system of claim 23, wherein the control is configured to energize the x-ray source at different angular positions relative to the breast when the source is stationary relative to the breast at each of a number of said positions.

29. The system of claim 23, wherein the processor is configured to form at least some of the tomosynthesis images to conform to image planes that are generally parallel to that of the mammogram position.

30. The system of claim 23, wherein the processor is configured to form at least some of the tomosynthesis images to conform to image plane that are non-parallel to that of the mammogram position.

31. The system of claim 23, wherein the control is configured to place the source at said mammogram position at an angle of substantially 0° at which a center ray of the x-rays is substantially normal to the x-ray imager.

32. The system of claim 23, wherein the control is configured to place the source for taking image data for said mammogram position before taking image data for the tomosynthesis positions.

33. The system of claim 23, wherein the control is configured to place the source for taking image data for the mammogram position after taking image data for the tomosynthesis positions.

34. The system of claim 23, wherein the control is configured to place the source for taking image data for the mammogram position after taking image data for some of the tomosynthesis positions but before taking image data for other tomosynthesis positions.

35. The system of claim 23, wherein the control is configured to energize the source for taking image data for each of the tomosynthesis positions at substantially higher x-ray source kV compared with the kV used for acquiring the image data at the mammogram position.

36. The system of claim 23, wherein the source comprises a Tungsten x-ray target emitting x-rays toward said imager.

37. The system of claim 23, wherein the source is configured to emit x-rays at a kVp range substantially higher than 25 kVp when the imager is acquiring image data at least at some of said positions.

38. The system of claim 23, wherein the source is configured to emit x-ray in a range up to 50 kVp when the imager is acquiring image data for at least some said positions.

39. The system of claim 23, wherein the control is configured to move the source through angular positions that extend over a range of no more than 60°.

40. The system of claim 23, comprising at least one display configured for displaying the mammogram and tomosynthesis images for concurrent viewing.

41. The system of claim 23, comprising at least one display configured for displaying the mammogram and tomosynthesis images on the same screen.

42. The system of claim 23, comprising at least one display configured for displaying the mammogram and tomosynthesis images on adjacent screens.

43. The system of claim 23, wherein the processor is configured to form tomosynthesis images that represent thin slices of the breast that are essentially planar sections through the breast.

44. The system of claim 23, wherein the processor is configured to form tomosynthesis images that represent thick slices of the breast, about 5 to about 10 mm thick.
